Serum levels of fibroblast growth factor-21 are increased in chronic and acute renal dysfunction
Universität Leipzig, Dissertation
37 pages, 87 citations, 3 figures, 1 table, 5 appendices

The progressively increasing prevalence of the Metabolic Syndrome (MetS) has emerged as a major global health concern since the MetS is associated with an increased risk for cardiovascular morbidity and mortality. Central obesity represents a key feature of the MetS and is strongly related to all MetS comorbidities. Dysregulation of adipose tissue-derived proteins, so called adipokines, has been implied to partially contribute to these effects. Recently, fibroblast growth factor-21 (FGF-21) has been introduced as a novel insulin-sensitizing and weight-reducing adipokine with potential therapeutic properties. However, data on FGF-21 elimination are rather limited. Therefore, FGF-21 regulation in relation to renal function has been investigated in a patient population with chronic kidney disease (CKD, study population 1), as well as one with acute kidney impairment (study population 2).

In study population 1 (n = 499), patients were distributed into five CKD subgroups according to estimated glomerular filtration rate (eGFR). Median FGF-21 serum concentrations progressively increased from CKD stage 1 to stage 5 and highest values of FGF-21 were detected in stage 5 (1: 86.4 ng/l; 2: 206.4 ng/l; 3: 289.8 ng/l; 4: 591.3 ng/l; 5: 1918.1 ng/l). Furthermore, eGFR remained the strongest predictor for FGF-21 levels in multivariate analysis. For study population 2 (n = 32), blood samples were obtained before elective unilateral partial or total nephrectomy, as well as within 30 hours after surgery. In this population FGF-21 levels significantly increased after surgery (325.0 ng/l) as compared to before surgery (255.5 ng/l). Furthermore, relative changes of FGF-21 were independently and positively predicted by relative changes of creatinine in this cohort.

These results are in accordance with the hypothesis that FGF-21 is eliminated by the kidneys and that the extent of kidney dysfunction substantially contributes to serum FGF-21 levels. However, additional animal experiments and prospective clinical studies are needed to further elucidate the role of the kidneys in FGF-21 physiology.
2. Introduction

2.1 Adipokines – a link between body mass dyregulation and metabolic disturbances

In the last decades, dramatic increases in the prevalence of the Metabolic Syndrome (MetS) have become a major global health concern. Thus, in the United States of America its prevalence increased from 23.1% to 26.7% within 12 years. Likewise, the prevalence of the MetS is beyond 20% in Germany.

The MetS, also known as syndrome X and deathly quartet was primarily described in the late 1920s as a combination of hyperglycemia, hypertension, and gout in patients with a predisposition for metabolic disease states. In 1947, visceral adiposity has been integrated as an additional feature of this new syndrome. In 2001, the National Cholesterol Education Program (NCEP) has established a clinical definition for the MetS (Table 1) suitable for clinical practice and widely used today. In accordance with other well accepted definitions (World Health Organization, International Diabetes Federation), the NCEP defines insulin resistance and central obesity as key aspects of the MetS.

### Table 1. Clinical criteria for the diagnosis of the MetS adapted from the executive summary of the Third Report of the NCEP Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults

Onset of the MetS is associated with an increased risk for cardiovascular disease (CVD) including myocardial infarction and stroke and subsequently an increase in cardiovascular mortality.

Out of all components, central obesity is most strongly associated with the MetS and weight loss therapy remains the primary treatment for the MetS as it improves all MetS aspects as well as cardiovascular outcomes. Central obesity is defined as indicated in Table 1 and waist circumference is a reliable clinical predictor for the amount of visceral adipose tissue.
Adipose tissue mass mainly consists of adipocytes but also pre-adipocytes, endothelial cells, and immune cells, as well as intercellular matrix. In general, adipose tissue has significant impact on energy and glucose homeostasis. Thus, the presence of insulin leads to enhanced glucose uptake whereas lipolytic hormones stimulate the release of fatty acids in starvation periods.

Notably, adipose tissue has also been identified as an important endocrine regulator in the last decades, providing a potential link between adipose tissue mass dysregulation and the occurrence of the MetS. In this context, adipocytokines or adipokines are adipose tissue-secreted proteins with numerous functions in human metabolic processes. Thus, adipokines are involved in glucose homeostasis, insulin secretion, and the regulation of food intake. Furthermore, dysregulation of adipokines is present in diseases affecting these processes e.g. type 2 diabetes mellitus (T2DM), insulin resistance, and obesity. Important adipokines relevant to the present study will be introduced in more details within the next paragraphs.

The beginning of a new understanding of adipose tissue function has been marked by the discovery of the adipokine leptin. As early as 1950, Ingalls and co-workers introduced a then unknown gene mutation in mice which is associated with a morbidly obese phenotype: the ob gene. Weight gain in these mice is associated with massive overeating and leads to three times the body weight of healthy animals. In 1994 Zhang and co-workers reported the detection of a 16 kDa protein encoded by the ob gene and expressed almost exclusively in adipose tissue. The protein received the name leptin after the Greek word lepto, meaning thin. The leptin receptor has subsequently been detected in the choroid plexus of rodents and in high concentrations in the hypothalamus but it is also present in different tissues throughout the body. Soluble leptin binds to its receptor in the hypothalamic region and leads to a reduction of neuropeptide Y (NPY) mRNA expression a protein responsible for appetite and regulation of food intake. In health, leptin release from adipocytes is controlled by a negative feedback loop (Figure 1).
2. Introduction

Regulation of leptin release from adipose tissue in health

Figure 1. Simplified depiction of feedback processes for leptin release from adipocytes: In the fed state, increased leptin secretion leads to reduced NPY release. Subsequently, less food is consumed. In the fasted state decreased leptin concentrations lead to enhanced NPY release with increased food consumption.

These feedback mechanisms are extensively responsible for the balance between energy intake and energy expenditure. Hence, mutations of the ob gene result in weight gain and metabolic disturbances e.g., hyperglycemia and hyperinsulinemia in rodents.\(^\text{24}\) Leptin administration leads to decreases in body weight and ameliorates glucose imbalance in leptin-deficient ob/ob, mice.\(^\text{31}\) Paradoxically, ob/ob mice display limited progression of atherosclerosis\(^\text{32}\), whereas leptin administration results in worsening of atherosclerotic lesions.\(^\text{32}\) Apart from facets of the MetS, leptin is also involved in various processes including fertility\(^\text{23}\) and bone metabolism.\(^\text{33}\)

Along with the growing rates of obesity and T2DM, a lot of hope has been put into leptin as a therapeutic agent for facets of the MetS, especially due to the positive results of leptin administration on body weight of leptin-deficient rodents.\(^\text{34}\) In patients with lipodystrophy, a disorder characterized by leptin-deficiency, 4 months of subcutaneous leptin treatment in fact leads to improved lipid profile and reduced need of antidiabetic therapy.\(^\text{35}\) However, obese patients exhibit increased leptin gene expression in adipose tissue as compared to non-obese patients and levels of the adipokine highly correlate with body mass index.\(^\text{36}\) Furthermore, leptin levels predict worsening of the MetS independent from obesity.\(^\text{37}\) It is, therefore, postulated that obesity and other metabolic disturbances induce a leptin-resistant state comparable to insulin resistance in T2DM. Nonetheless, the pathophysiology behind the onset of leptin resistance remains unclear so far.

Another important adipokine closely linked to the MetS is adiponectin. Two years after the discovery of leptin, Maeda and co-workers demonstrated another gene almost exclusively and abundantly expressed in adipose tissue: the apM1 gene.\(^\text{38}\) Gene product is a 224 amino-acid, protein with similarities to collagen and complement 1q: adiponectin (apM1, AdipoQ).\(^\text{38}\) The
adipokine binds to two receptors, AdipoR1 and AdipoR2 with different expression patterns in mice and humans. AdipR1 is found ubiquitously whereas AdipR2 is predominantly expressed in the liver. Binding of the adipokine to its receptor leads to enhancements in fatty acid oxidation in skeletal muscle and liver cells, as well as stimulation of glucose uptake in skeletal muscle cells. Therefore, adiponectin is considered to be an adipokine with beneficial effects on glucose and lipid metabolism. In mouse 3T3-L1 preadipocytes, adiponectin mRNA expression increases considerably during differentiation and adiponectin stimulates adipocyte cell proliferation. Transgenic mice with adiponectin overexpression exhibit increased energy expenditure, a beneficial lipid profile, low blood glucose levels, and considerable decreases in adipocyte differentiation. In obese mice, levels of adiponectin are extensively decreased as compared to lean controls. Apart from obesity, plasma adiponectin levels are significantly reduced in various metabolic disturbances in rodents and primates. Adiponectin knockout mice display diet-induced insulin resistance and serum levels of the adipokine correlate inversely with the degree of insulin resistance in monkeys. In concordance with these results in animals, adiponectin concentrations are considerably decreased in humans with facets of the MetS as compared to normal-weight subjects. Furthermore, plasma adiponectin levels are reduced in diabetic patients as compared to healthy controls. Moreover, adiponectin concentrations are an independent predictor for the occurrence of the MetS and are negatively associated with blood pressure in 21,000 healthy subjects.

Since CVD represents the leading cause for MetS-associated morbidity and mortality, the role of adiponectin in CVD has been subject to through investigations by different groups. Interestingly, adiponectin has anti-atherogenic effects. Mechanisms for these beneficial effects of adiponectin include anti-inflammatory properties and decreased tumor necrosis factor (TNF) α-induced monocyte adhesion. Since patients with CVD generally exhibit low levels of adiponectin, hypoadiponectaemia in the MetS might contribute to increased risk for cardiovascular events.

Apart from adiponectin, chemerin represents an additional adipokine with metabolic, as well as chemotactic, properties. Chemerin was primarily discovered in the 1990’s as a product of the tazarotene-induced gene 1 or retinoid acid receptor responder 2, a gene responsive to retinoid acid treatment in psoriasis, an inflammatory skin disease. The adipokine is ligand to three different receptors: chemokine receptor-like 1 (CMKLR1), chemokine receptor-like 2 (CCRL2), and G protein-coupled receptor 1 (GPCR1) with different expression patterns.
throughout the body. CMKLR1 is predominantly expressed in white adipose tissue of mice, whereas high concentrations of CCRL2 and GPCR1 are found in rodent skeletal muscle cells. While CCRL2 and GPCR1 function remains to be elucidated, binding of chemerin to the CMKLR1 stimulates migration of macrophages and immature dendritic cells to sites of injury \textit{in vitro}. Furthermore, similar to adiponectin, chemerin is induced during adipocyte differentiation \textit{in vitro}. Moreover, incubation of 3T3-L1 preadipocytes with chemerin significantly increases insulin-stimulated glucose uptake. Extensive studies in leptin-deficient \textit{ob/ob} and leptin receptor-deficient \textit{db/db} mice, which serve as models for obesity and T2DM, demonstrate significant increases in total chemerin concentration and decreases in CMKLR1 expression in white adipose tissue as compared to healthy mice. Furthermore in contrast to \textit{in vitro} studies, chemerin administration results in aggravation of glucose intolerance by decreasing glucose uptake and insulin secretion in obese, as well as diabetic, mice.

Chemerin concentrations correlate positively with markers of inflammation, e.g. C-reactive protein (CRP), interleukin-6 (IL-6), and TNF-\(\alpha\) in human subjects. Circulating chemerin is significantly and positively associated with multiple facets of the MetS. However, chemerin regulation in insulin resistance, as well as CVD, in humans remains controversial. Thus, Spiroglou and co-workers reveal a positive association between chemerin levels and coronary atherosclerosis whereas no association is seen in another study. Furthermore upregulation and no regulation of the adipokine in T2DM have been reported.

2.2 Fibroblast growth factor-21 – a novel adipokine with beneficial properties

The fibroblast growth factor (FGF) family is a group of proteins with various effects on human and animal cells including, angiogenesis, embryogenesis and regulation of cell survival. With first recognition in 1974, to date the FGF family consists of 22 members, which can be further subcategorized into three groups: intracellular, paracrine, and hormone-like subfamily. Extensive research during the last decades is only beginning to elucidate the role of the hormone-like subfamily members, e.g. FGF-15, FGF-21 and FGF-23, in human metabolic processes.

FGF-21 is a 181 amino acid protein which binds to the FGF receptor, a transmembrane tyrosine kinase, in a \(\beta\)-Klotho dependent manner. FGF-21 was initially identified in liver and thymus tissue of mouse embryos by Nishimura and co-workers in 2000. Soon after, adipose tissue has been revealed as an additional source of FGF-21 expression. Research on FGF-21 action in adipose tissue demonstrates progressive increases in FGF-21 mRNA
expression during adipogenesis.\textsuperscript{62} Furthermore, FGF-21 mediates insulin-independent stimulation of glucose uptake in differentiated adipocytes.\textsuperscript{63} In more detail, binding of the adipokine to the FGF receptor induces an intracellular signal cascade leading to increased glucose transporter (GLUT)-1 gene expression.\textsuperscript{64} Subsequent translocation of GLUT-1 generates increased glucose uptake in adipocytes.

In animal models, FGF-21 mRNA expression increases in adipose tissue and liver of diet-induced obese mice and treatment with FGF-21 reduces body weight and ameliorates insulin resistance in these mice.\textsuperscript{65,66} Administration of FGF-21 to diabetic primates leads to improved serum glucose and lipid profiles.\textsuperscript{67}

It is apparent that due to its beneficial effects on insulin resistance, central obesity, and serum lipids in rodents, FGF-21 functions as a potential pharmacological target for the treatment of these metabolic disturbances seen in the MetS. Therefore, over the past years, several studies have focused on FGF-21 regulation in human subjects with components of the MetS. In this context, data of FGF-21 serum levels in patients with T2DM, an insulin resistant state, reveal significant upregulation of the adipokine as compared to healthy controls.\textsuperscript{68,69} Furthermore, two independent studies show elevated FGF-21 levels in obese as compared to normal-weight subjects.\textsuperscript{62,70} Notably, FGF-21 independently predicts the occurrence of the MetS in a longitudinal study with 440 patients.\textsuperscript{71} Furthermore, Zhang and co-workers demonstrate a progressive increase in FGF-21 levels with increasing number of MetS components.\textsuperscript{62}

The paradoxical increase of the beneficial adipokine FGF-21 in humans with facets of the MetS is subject of ongoing investigations. It appears that FGF-21 resistance in the MetS, similar to leptin resistance, is at least partially accountable for this upregulation. Additionally and alternatively, FGF-21 induction might be a compensatory response to limit the adverse consequences of MetS components on metabolic and vascular health.
2.3 Adipokines and renal function

The kidneys are substantially involved in the regulation of various processes in humans. Apart from adjusting blood pressure, as well as maintaining acid-base and fluid balance, filtration of blood followed by excretion of waste products is another important task.

According to the *Kidney Disease: Improving Global Outcomes* criteria, chronic kidney disease (CKD) is defined as abnormalities of kidney structure or function, present for more than three months, alongside implications for health. The deterioration of renal function substantially contributes to an increased risk for CVD and premature death. Several features of patients with MetS, such as T2DM and hypertension have long been held accountable for these adverse outcomes in patients with CKD. However, recent studies suggest additional pathophysiological mechanisms responsible for the increase in cardiovascular events in patients with impaired renal function. It has been demonstrated, that diminished elimination of adipokines in patients with kidney function impairment significantly adds to the occurrence of CVD. Therefore, adipokine regulation in relation to renal function has been subject to profound investigations over the last years.

In this context, Cumin and co-workers have been among the first groups to provide substantial evidence that *leptin* is eliminated by the kidneys by performing bilateral nephrectomy as compared to sham operation in rats. In more detail, levels of the adipokine spike significantly and immediately after the surgery and progressively increase within the next 48 h. Gel electrophoresis further shows that leptin levels are decreased in venous as compared to arterial renal blood and extraction rate is calculated at 45%. However, only small amounts of leptin are found in urine suggesting renal metabolization rather than excretion. In humans, Sharma and co-workers have quantified leptin levels in human aortic and renal vein blood. Leptin concentrations are decreased by 12 % in renal vein as compared to aortic blood in healthy patients whereas leptin levels remain constant in patients with mild to moderate stages of CKD. Moreover, serum levels of the adipokine are 4.5 fold increased in a second cohort with end-stage renal disease (ESRD). Notably, leptin serum concentrations significantly and negatively correlate with glomerular filtration rate. Since leptin is considerably contributing to worsening of atherosclerosis, it has been suggested that hyperleptinaemia seen in patients with deteriorating renal function should be subject to therapeutic intervention. In contrast, *adiponectin* is associated with a beneficial metabolic and cardiovascular profile. Animal studies of renal function-associated adiponectin regulation have revealed hyperadiponectinaemia in male mice one month after subtotal nephrectomy.
nephrectomy. Furthermore, injection of wild type plasma to adiponectin knockout mice reveals lower adiponectin clearance rates in nephrectomized as compared to sham-operated mice, again indicating renal elimination of the adipokine. In humans, deterioration of renal function results in progressive elevation of serum adiponectin levels and patients with ESRD receiving kidney transplants exhibit lower levels of adiponectin after as compared to before transplantation. Since a beneficial role of the adipokine in CVD is implied, several studies focus on hyperadiponectaemia in renal disease in relation to cardiovascular events. However, data remain controversial. Thus, Becker and co-workers demonstrate low adiponectin levels as a risk factor for cardiovascular events in a prospective study of patients with renal dysfunction. In contrast, a decreased risk for cardiovascular mortality is shown in patients with low adiponectin concentrations in another study. In accordance with studies on leptin and adiponectin, chemerin serum concentrations are also upregulated in humans with impaired renal function. Recently, our group has demonstrated significant upregulation of the adipokine in patients undergoing chronic hemodialysis as compared to healthy controls. In this study, estimated glomerular filtration rate (eGFR) remains an independent predictor for circulating chemerin in ESRD patients. In accordance with our findings, Yamamoto and co-workers also reveal a negative correlation between chemerin and eGFR in a study population of 252 patient with CKD stage 5. Notably in a 5-year follow-up, high chemerin levels at baseline have predicted a better overall survival. In addition, ESRD patients exhibit 30% higher chemerin serum levels before as compared to after receiving kidney transplant.

2.4 FGF-21 and renal function
In contrast to these well-described adipokines, i.e. leptin, adiponectin, and chemerin, data on FGF-21 regulation in relation to renal function are particularly limited. Thus, our group has been the first to describe an association between the adipokine and renal function in a small study population of patients undergoing chronic hemodialysis (n = 120). Data on these patients with extensively diminished renal function revealed significant increases in FGF-21 levels in comparison with healthy controls. Furthermore, eGFR negatively predicts levels of the adipokine. In agreement with these findings, Lin and co-workers demonstrate increased FGF-21 serum concentrations in a small patient population with severe as compared to mild CKD. However, patient numbers in these studies have been rather small and none of the studies covered all stages of CKD. Furthermore, to the best of our knowledge, no data are available on FGF-21 regulation in patients with acute kidney injury. To address these limitations, FGF-21 serum concentrations were quantified in a large cohort of 499 patients.
covering CKD stages 1 to 5. Furthermore, we measured FGF-21 levels in 32 patients undergoing elective partial or total unilateral nephrectomy. Moreover, in both study populations, FGF-21 levels were correlated with biochemical and anthropometric measures of renal function, inflammation, glucose metabolism, and lipid metabolism. We hypothesized that:

1. FGF-21 levels progressively increase with increasing CKD stage in humans.
2. FGF-21 serum concentrations increase in patients with acute kidney injury.
3. Methods and Results

3.1 Research design and Methods
To address the hypotheses summarized in 2.4. two different study populations were recruited.

**Study population 1** consisted of 499 patients (men: n = 280; women: n = 219) with varying degrees of CKD (1: n = 48; 2: n = 88; 3: n = 128; 4: n = 54; 5: n = 181). Stages of CKD were defined according to the Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines. Thorough clinical examination and questionnaire on past medical history were conducted prior to the collection of blood samples under fasting conditions (> 8 hours after last meal). In patients on hemodialysis, blood samples were taken before hemodialysis started.

**Study population 2** included 32 patients (men: n = 26; women: n = 6) from the Department of Urology, University of Leipzig, undergoing partial or total unilateral nephrectomy. Again, patients received a thorough clinical examination and a questionnaire on past medical history was completed. Blood samples under fasting conditions were taken prior to surgery, as well as within 30 hours after surgery.

In both study populations, biochemical parameters were measured by the Institut für Labormedizin, Klinische Chemie und Molekulare Diagnostik, Leipzig. Levels of adiponectin, leptin, and FGF-21 were quantified by commercial enzyme-linked immunoabsorbant assays. Written informed consent was obtained from all patients. Statistical analyses were conducted using SPSS software version 20.0.
3.2 Results
In study population 1, median FGF-21 serum levels progressively increased from CKD stage 1 to CKD stage 5 (1: 86.4 ng/l; 2: 206.4 ng/l; 3: 289.8 ng/l; 4: 591.3 ng/l; 5: 1918.1 ng/l). Significant increases are depicted in Figure 2.

![Figure 2. Median values (interquartile range) of FGF-21 serum concentrations in relation to CKD stage according to the KDOQI guidelines (n = 499). * indicates statistical significance (p < 0.05).](image)

Furthermore, patients with diabetes mellitus exhibited significantly higher values of FGF-21 (619.7 ng/l) as compared to patients without diabetes (437.1 ng/l) (p = 0.003). Moreover, men (552.1 ng/l) had significantly higher levels of FGF-21 as compared to women (441.2 ng/l) (p = 0.020). Univariate correlation method revealed significant and positive associations between FGF-21 on one hand and age, waist-to-hip ratio (WHR), waist-to-height ratio, serum creatinine, triglycerides, high sensitivity (hs)CRP, hsIL-6, leptin, and adiponectin on the other hand. Furthermore, a significant and negative correlation was present between FGF-21 levels and diastolic blood pressure, eGFR, fasting glucose, cholesterol, HDL cholesterol, and low-density lipoprotein (LDL) cholesterol. In multivariate regression analysis, the renal marker eGFR remained the strongest negative predictor for FGF-21 levels. Furthermore, a negative
association was observed with LDL cholesterol whereas a positive association between FGF-21 levels on the one hand and WHR, triglycerides, and adiponectin on the other hand persisted in multiple regression analysis.

In study population 2, Median FGF-21 levels significantly increased in patients after unilateral partial or total nephrectomy (325.0 ng/l) as compared to before surgery (255.5 ng/l) (p < 0.05) (Figure 3).

![Figure 3.Median (interquartile range) FGF-21 serum concentrations in patients before and after unilateral partial or total nephrectomy (n = 32). * indicates statistical significance (p < 0.05) assessed after Wilcoxon signed-rank test.](image)

Furthermore, creatinine, hsCRP and hsIL-6 significantly increased whereas eGFR, levels of triglycerides, cholesterol, HDL and LDL cholesterol and adiponectin significantly decreased after surgery. Moreover, relative changes (post-to-presurgery) of FGF-21 serum concentrations correlated negatively with relative changes of eGFR and positively with relative changes of creatinine in univariate analysis. In addition, relative changes of creatinine remained a strong predictor for relative changes of FGF-21 levels in multivariate analysis even after adjustment for age and gender (p < 0.001).

These results support the hypothesis that FGF-21 levels in humans are closely linked to renal function, assessed as eGFR, in patients with CKD, as well as acute renal dysfunction. Furthermore, eGFR is an independent predictor for FGF-21 serum concentrations in these two patient populations.

Original Article

Summary

Objective Fibroblast growth factor (FGF)-21 has recently been introduced as a circulating adipokine which reverses insulin resistance and obesity in rodents. In this study, regulation of FGF-21 in renal dysfunction was elucidated in both chronic kidney disease (CKD) and acute kidney dysfunction (AKD).

Study design and methods Serum concentrations of total FGF-21 were quantified by enzyme-linked immunosorbent assay in 499 patients with CKD stages 1–5 (study population 1). Furthermore, total FGF-21 was determined before and within 30 h after unilateral nephrectomy, a model of AKD, in 32 patients (study population 2). FGF-21 levels were correlated to anthropometric and biochemical parameters of renal function, glucose and lipid metabolism, as well as inflammation, in both studies.

Results In study population 1, median [interquartile range] circulating FGF-21 adjusted for age, gender and body mass index was significantly different between CKD stages with highest values detectable in stage 5 (stage 1: 86.4 [132.9]; 2: 206.4 [223.1]; 3: 289.8 [409.3]; 4: 591.3 [789.0]; 5: 1918.1 [4157.0] ng/l). Furthermore, estimated glomerular filtration rate remained a strong independent and negative predictor of FGF-21. In study population 2, FGF-21 increased significantly postsurgically (325.0 [984.0] ng/l) as compared to presurgical values (255.5 [243.0] ng/l). Furthermore, relative changes of FGF-21 were independently and positively predicted by relative changes of creatinine.

Conclusions We demonstrate that circulating FGF-21 is increased in both CKD and AKD. Our results suggest renal excretion as a major route for FGF-21 elimination. The pathophysiological significance of these findings needs to be elucidated in more detail.

Introduction

Various adipocyte-secreted factors, so-called adipokines, contribute to facets of the metabolic syndrome (MetS). Thus, the adipokine adiponectin induces a beneficial metabolic profile. In contrast, the appetite-suppressive adipokine leptin is upregulated in obesity and associated with an increased risk of cardiovascular disease (CVD). Furthermore, the adipokine interleukin-6 induces insulin resistance and is associated with risk factors for CVD in humans.

Recently, fibroblast growth factor (FGF)-21, a member of the FGF family, has been introduced as an adipokine stimulating glucose uptake in adipocytes and increasing insulin sensitivity in rodents. However, the adipokine is paradoxically upregulated in various metabolic disease states in human subjects. Thus, Lin et al. have revealed upregulation of FGF-21 in 135 patients with coronary heart disease as compared to healthy controls. Moreover, Chavez et al. demonstrated increased FGF-21 serum levels in patients with type 2 diabetes mellitus as compared to healthy controls. Taking these studies into account, FGF-21 appears to be an adipokine with multiple beneficial metabolic effects in rodents. However, exact mechanisms of FGF-21 upregulation in human metabolic disease remain unclear.

In contrast to these extensive studies in human metabolic disease, elimination of FGF-21 has not been studied in detail so far. Most importantly, previous studies on FGF-21 and renal function show the following limitations: none of the studies (i) included >250 patients; (ii) covered the whole spectrum of renal dysfunction ranging from CKD stages 1–5 comprehensively; and (iii) elucidated the role of acute decreases in kidney function on FGF-21 serum levels. To address these issues and to more definitely define the role of the kidney in FGF-21 elimination, we quantified FGF-21 serum concentrations in 499 patients covering the whole spectrum of CKD (study population 1).
Furthermore, we evaluated for the first time FGF-21 serum levels in 32 patients before and after unilateral partial or total nephrectomy (study population 2). Moreover, we correlated the adipokine to clinical and biochemical parameters of renal function, glucose and lipid metabolism, as well as inflammation.

We hypothesized that FGF-21 serum concentrations (i) increase with deteriorating renal function in CKD (study population 1) and (ii) are increased in acute renal dysfunction after nephrectomy (study population 2).

Research design and methods

Subjects

**Study population 1.** For this cross-sectional study, 532 patients (men: n = 305; women: n = 227) were recruited between 2006 and 2010 by the Department of Endocrinology and Nephrology, University of Leipzig, and from three outpatient Nephrology Care Units (Hospital St. Georg, Division of Nephrology, KIH Renal Unit, 04129 Leipzig; outpatient Nephrology Care Units, 04107 and 04178 Leipzig) as described in detail recently. Prior to analyses, all patients on peroxisome proliferator-activated receptor (PPAR)α- and PPARγ-agonists were excluded, and 499 patients remained in the study. Study participants underwent a thorough examination including anthropometric measures of obesity (waist and hip circumference, height, body mass index [BMI], waist-to-hip ratio [WHR] and waist-to-height ratio [WHtR]), hypertension and a standardized questionnaire on past medical history. Furthermore, blood samples were drawn after an overnight fast at the respective care units. In haemodialysis patients, blood samples were taken right before haemodialysis started. Age of the study population was between 19 and 92 years, and BMI ranged from 18 to 37 kg/m². Estimated glomerular filtration rate (eGFR) was calculated according to the Modification of Diet in Renal Disease (MDRD) formula, and all patients were classified into chronic kidney disease (CKD) stages 1–5 according to the National Kidney Foundation – Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines. Homeostasis model assessment of insulin resistance (HOMA-IR) was determined as described.

**Study population 2.** For this longitudinal cohort, 32 patients (men: n = 26; women: n = 6) undergoing elective partial or total unilateral nephrectomy were recruited by the Department of Urology and the Department of Endocrinology and Nephrology, University of Leipzig. Recent studies convincingly demonstrated that these patients serve as a model for acute kidney dysfunction (AKD). The study design was described recently. Indications for surgery included renal carcinoma, renal shrinkage and renal cysts. The following inclusion and exclusion criteria were applied: inclusion criteria, age between 18 and 80 years; and exclusion criteria, haemodialysis, hereditary renal cysts, glomerulonephritis and generalized inflammation. Blood samples under fasting conditions were obtained shortly before renal surgery (05:00 [0:22] AM). Age of the study population ranged from 22 to 78 years and BMI from 18.2 to 37.0 kg/m². Anthropometric data (BMI, WHR and WHtR), as well as HOMA-IR, were assessed as described previously. For this population, eGFR was calculated using the Chronic Kidney Disease Epidemiology Collaboration formula including four parameters (serum creatinine, gender, race and age).

Both studies were approved by the local Ethics Committee, and written informed consent was obtained from all patients before taking part in the studies.

Assays

Serum concentrations of total FGF-21 were determined with a commercial enzyme-linked immunosorbent assay (ELISA) from Biovendor (Modrice, Czech Republic). Intra- and interassay coefficients were <4.1% and 3.9%, respectively. Sensitivity was 7 ng/l, and the ELISA was specific for human FGF-21 with no cross-reactivity with human FGF-19 and human FGF-23. Normal median FGF-21 levels for patients beyond 30 years of age were given by the manufacturer as follows: female 222–2 ng/l and male 237–4 ng/l. Leptin was quantified with a high-sensitivity ELISA from Mediapost (Reutlingen, Germany). Intra- and interassay coefficients were <4.4% and 7.5%, respectively. Sensitivity was 0.2 ng/l, and the ELISA was specific for human leptin with no cross-reactivity to other proteins such as insulin or insulin-like growth factor-1. Normal median leptin levels for subjects with a BMI of 25 kg/m² were given by the manufacturer as follows: female 11–9 µg/l and male 3–18 µg/l. Total adiponectin was determined with an ELISA from Mediagnost (Reutlingen, Germany). Intra- and interassay coefficients were <4.7% and 6.7%, respectively. Sensitivity was 0.6 µg/l, and the ELISA was specific for human adiponectin with no cross-reactivity to other species. Normal median adiponectin levels were given by the manufacturer as follows: female 9.1 mg/l and male 6.1 mg/l. Total rather than other molecular isoforms of adiponectin, for example high molecular weight adiponectin, was quantified in this study as most analyses in the literature concerning adiponectin and metabolic disease have been performed with assays quantifying total protein. In all patients, serum concentrations of high-sensitivity interleukin-6 (hsIL-6) were determined with a commercial ELISA from R&D Systems (Minneapolis, MN, USA) according to the manufacturer’s instructions. Intra- and interassay coefficients were less than 4.2% and 6.4%, respectively. Sensitivity was 0.7 ng/l, and the ELISA was specific for human IL-6 with no cross-reactivity to other species and interleukins. Serum creatinine, fasting glucose (FG), fasting insulin (FI), triglycerides (TG), cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol and high-sensitivity C-reactive protein (hsCRP) were measured in a certified laboratory by standard methods.

Statistical analysis

SPSS software version 20.0 (IBM, Armonk, NY, USA) was used for all statistical analyses.
In study population 1, overall group differences for continuous parameters were assessed by Kruskal–Wallis test followed by post-hoc analysis with prior adjustment for age, gender and BMI. Univariate correlations were assessed by nonparametric Spearman’s rank correlation method. Furthermore, multivariate linear regression analysis was performed. Prior to the multivariate analysis, distribution of continuous variables was tested for normality using the Shapiro–Wilks test, and non-normally distributed parameters were logarithmically transformed.

In study population 2, differences in FGF-21 serum concentrations and other laboratory parameters before and after renal surgery were assessed by Wilcoxon signed-rank test for related samples. Furthermore, relative changes (post-surgical-to-presurgical ratios) were calculated for all laboratory parameters as follows: parameter (post-surgery) / parameter (presurgery) similar to other studies. Univariate correlation analysis was performed by Spearman’s rank correlation method using these relative changes (ratios). Afterwards, multivariate linear regression analysis was performed as described previously. In all multivariate linear analyses, parameters that correlated significantly with FGF-21 in univariate analysis were included. For covariates, for example creatinine and eGFR, the parameter with the strongest univariate correlation was included in the multivariate model. Furthermore, age and gender were included in all multivariate analyses. A P-value of <0.05 was considered as statistically significant in all analyses.

Results

Study population 1

FGF-21 serum concentrations are increased in patients with CKD. The clinical characteristics of the five CKD subgroups studied are summarized in Table 1. Median [interquartile range] FGF-21 levels were 512.7 [1204.1] ng/l in the total study population. FGF-21 levels were significantly different between the five CKD stages (P < 0.001). Serum FGF-21 concentrations increased with deteriorating renal function, and highest values were seen in CKD stage 5 (Table 1). When patients were divided according to diabetes mellitus status, circulating median [interquartile range] FGF-21 was significantly higher in patients with diabetes mellitus (619.7 [1696.8] ng/l) as compared to nondiabetic subjects (437.1 [1147.3] ng/l) (P = 0.003). In contrast, FGF-21 was not significantly different between overweight/obese patients (476.6 [1094.5] ng/l) as compared to lean subjects (555.2 [1738.0] ng/l) (P = 0.492). Moreover, FGF-21 levels were significantly higher in men (552.1 [1570.1] ng/l) as compared to women (441.2 [797.1] ng/l) (P = 0.020). In

BMI, body mass index; CKD, chronic kidney disease; DBP, diastolic blood pressure; eGFR, estimated glomerular filtration rate; FG, fasting glucose; FGF-21, fibroblast growth factor-21; FJ, fasting insulin; HDL, high-density lipoprotein; HOOMA-IR, homeostasis model assessment of insulin resistance; hsCRP, high-sensitivity C-reactive protein; hsIL-6, high-sensitivity interleukin-6; LDL, low-density lipoprotein; SBP, systolic blood pressure; TG, triglycerides; WHR, waist-to-hip ratio; WHIR, waist-to-height ratio. Values for median (interquartile range) or total number (percentage) are shown. Continuous parameters were adjusted for age, gender and BMI and analysed by Kruskal–Wallis test followed by post-hoc analysis. Numbers in superscript indicate P < 0.05 as compared to CKD stage 1, 2, 3 or 4.
addition, patients with pre-existing CVD, that is coronary heart disease, chronic heart failure, stroke or peripheral arterial disease, had significantly higher FGF-21 concentrations (711.1 [1693-6] ng/l) as compared to subjects without CVD (400.9 [941-3] ng/l) (P < 0.001).

Univariate correlations. Circulating FGF-21 was significantly and positively associated with age, WHR, WHIR, serum creatinine, TG, hsCRP, hsIL-6, leptin and adiponectin (Table 2). In contrast, FGF-21 serum concentrations in this population were significantly and negatively correlated with DBP, eGFR, FG, cholesterol, HDL cholesterol and LDL cholesterol (Table 2).

Multivariate regression analysis. After adjustment for age and gender, multivariate regression analysis of study population 1 revealed that serum FGF-21 levels remained strongly and negatively associated with eGFR independent of DBP, WHR, TG, HDL cholesterol, LDL cholesterol, hsIL-6 and adiponectin (Table 2). Furthermore, circulating FGF-21 remained negatively and independently associated with LDL cholesterol (Table 2). Moreover, an independent and positive association was observed between FGF-21 on one hand and WHR, TG and hsIL-6 on the other hand (Table 2). In addition, results were virtually identical when statin treatment or pre-existing CVD was included as additional covariates in the multivariate model (data not shown). It is interesting to note that statin treatment but not pre-existing CVD was an independent predictor of circulating FGF-21 (data not shown). Furthermore, WHIR and hsCRP were significant and positive predictors of circulating FGF-21 when included in the model instead of WHR and hsIL-6, respectively (data not shown).

Study population 2

FGF-21 serum levels are increased in patients after unilateral partial or total nephrectomy. Table 3 summarizes baseline characteristics of study population 2, as well as laboratory parameters before and after nephrectomy. FGF-21 serum levels were significantly increased in patients after unilateral partial or total nephrectomy (325.0 [984.0] ng/l) as compared to presurgical concentrations (255.5 [243.0] ng/l) (P < 0.001) (Table 3). Furthermore, creatinine hsCRP and hsIL-6 were significantly increased in patients after unilateral partial or total nephrectomy.

significantly increased in patients after renal surgery, whereas eGFR, TG, cholesterol, HDL cholesterol, LDL cholesterol and adiponectin decreased significantly (Table 3).

Univariate correlations. Relative changes (postsurgical-to-presurgical ratios) in FGF-21 levels were positively and significantly correlated with creatinine (ratio) (Table 4). Furthermore, eGFR (ratio) was negatively and significantly associated with FGF-21 (ratio) (Table 4).

Multivariate regression analysis. Even after adjustment for age and gender, FGF-21 (ratio) remained positively associated with creatinine (ratio) in multivariate regression analysis (Table 4). In addition, results were virtually the same when hsCRP or hsIL-6 were included as markers of inflammation in the multivariate model (data not shown).

Discussion

In the present study, we demonstrate that FGF-21 levels increase with deteriorating renal function in a large (n = 499) cohort covering the whole spectrum of CKD stages (study population 1) for the first time. Furthermore, renal function is the strongest independent predictor of FGF-21 in this cohort. Moreover, we show that the adipokine is significantly and acutely upregulated in patients after unilateral partial or total nephrectomy (study population 2), a model for AKD.13,14 Interestingly, relative changes of FGF-21 (postsurgical-to-presurgical ratio) are positively and independently associated with relative changes in creatinine (postsurgical-to-presurgical ratio) in this cohort. These findings support the hypothesis that renal excretion is a major route for eliminating FGF-21 from circulation. It needs to be pointed out that median time at blood sampling is not the same for the presurgical and postsurgical measurements. Therefore, an effect of circadian rhythm on our results cannot be excluded with certainty; however, FGF-21 concentrations at both time points are similar according to evidence published by Yu et al.20 Furthermore, circulating FGF-21 does not appear to be dialysable as it is significantly higher after as compared to before haemodialysis (data not shown).

Our findings suggest that markers of renal function, for example creatinine or eGFR, should be included in all studies on FGF-21 physiology. In agreement with our present findings, we and others have recently shown upregulation of circulating FGF-21 in end-stage renal disease. Furthermore, Lin et al.8 demonstrate significantly increased FGF-21 levels in patients with severe CKD as compared to mild CKD and controls. Animal studies are necessary to elucidate which mechanisms contribute to renal elimination of FGF-21 and to determine the physiological relevance of increased FGF-21 levels in acute and chronic renal dysfunction.

Animal experiments demonstrate convincingly that FGF-21 is an insulin-sensitizing and lipid-lowering adipokine which increases energy expenditure.2 Thus, Sarruf et al.21 have recently shown that intracerebroventricular administration of FGF-21 in obese rats results in improved hepatic insulin sensitivity through suppression of hepatic glucose production and gluconeogenic gene expression. In agreement with these findings, Khartonovenkov et al.22 reveal that FGF-21 transgenic mice are resistant to diet-induced obesity. Most interestingly, FGF-21 increases adiponectin secretion in rodents in a very recent paper by Holland et al.23 In more detail, administration of FGF-21 to obese wild-type mice results in extensive weight loss and improved glucose homeostasis.21 In contrast, these beneficial effects are not observed in obese adiponectin knockout mice suggesting adiponectin-dependent FGF-21 action in rodents.21 In our study population 1, FGF-21 shows a positive correlation with adiponectin in univariate analysis and a trend towards an independent positive association in multivariate analysis supporting the hypothesis that upregulation of adiponectin is FGF-21-mediated. Furthermore, administration of FGF-21 in diabetic primates results in a significant decline of fasting plasma glucose, as well as decreased TG and LDL cholesterol levels.22 Moreover, Coskun et al.23 show convincingly that FGF-21-treated obese mice exhibited increased energy expenditure, fat utilization and lipid excretion. Taking these findings into consideration, it is tempting to speculate that increased circulating FGF-21 in acute and chronic

Multivariate regression analysis of FGF-21 (ratio, dependent variable) and age, gender, as well as creatinine (ratio) in all patients. Non-normally distributed variables were logistically transformed prior to multivariate testing. r and P-values, as well as standardized β-coefficients and P-values, are given. Abbreviations are indicated in Table 1. * indicates significant correlation as assessed by Spearman’s rank correlation method. † indicates significant correlation in multivariate analysis.
renal dysfunction might limit the adverse metabolic and vascular effects of the disease. Alternatively, FGF-21 resistance might be present in acute and chronic renal dysfunction similar to insulin resistance seen in obesity. It is interesting to note in this context that FGF-21 resistance has already been described in obesity. In more detail, Fisher et al. show convincingly that FGF-21 mRNA expression increases in the liver and in white adipose tissue of obese mice. Furthermore, activation of the FGF-21 signalling pathways and FGF-21 mediated early gene transcription is impaired in obese mice. Clearly, more mechanistic studies are needed to better elucidate the physiological role of increased FGF-21 in acute and chronic kidney dysfunction.

In accordance with results obtained in obese rodents, we show a strong, positive and independent correlation between serum FGF-21 levels and WHR as a marker of adverse fat distribution in study population 1. This is in accordance with a study by Zhang et al. They reveal a positive association between FGF-21 levels and WHR even after adjustment for age and BMI in their study comprising 232 subjects. Similarly, FGF-21 is positively and independently correlated with WHR in the present study which is an alternative marker for adverse body fat distribution. Interestingly, FGF-21 is not significantly associated with BMI and is not different between overweight/obese patients as compared to lean subjects. Because WHR and WHHR better reflect adverse body fat distribution as compared to BMI, it is tempting to speculate that an accumulation of visceral fat rather than increased body fat mass leads to a FGF-21 resistant state. Clearly, future studies are needed to determine the pathophysiological significance of FGF-21 upregulation/resistance in metabolic diseases.

In study population 1, FGF-21 correlates positively and independently with further markers of the MetS including TG and hsCRP similar to other reports. In contrast to other studies, FGF-21 does not correlate with measures of insulin resistance including FI and HOMA-IR. Interestingly, LDL cholesterol correlates paradoxically and negatively with circulating FGF-21 in study population 1 in multivariate analyses. These data are in accordance with a recent study from our group in pregnant women. It is interesting to note in this context that FGF-21 increases LDL-receptor expression in cultured human hepatocytes leading to an enhanced lipoprotein uptake. However, it needs to be pointed out that other data suggest a positive association between LDL cholesterol and FGF-21 levels in contrast to our findings. Differences in patient characteristics with regard to age, gender, renal function, ethnicity and phenotyping might well explain the different findings.

In contrast to FGF-21, adiponectin levels significantly decline during surgery are paradoxical as its secretion is stimulated by FGF-21, and its renal clearance is likely to be reduced postoperatively. Clearly, the causes for this unexpected regulation need to be elucidated in future studies.

There are some limitations of the study that need to be emphasized. First, a cross-sectional design is used for study population 1, and therefore, causality cannot be established. Second, the sample size of study population 2 is rather small, and it is quite possible that various non-significant associations in multivariate analyses would have become statistically significant if larger samples were studied. Third, we cannot exclude the possibility that confounding factors that influence circulating FGF-21 have not been considered. Fourth, no information is available in the present study concerning specific FGF receptors and β-klotho in target tissues through which biologically active FGF-21 acts.

Taken together, we demonstrate for the first time that circulating FGF-21 is increased in both CKD and AKD. Our results support the hypothesis that renal excretion is a major route to eliminate FGF-21 from circulation. The pathophysiological significance of these findings needs to be elucidated in more detail.

Author contributions
J.H., T.E. and M.F. wrote the manuscript and researched data. A.B., J.K., J.U. S., A.D., J.B., M.A and I.B. researched data and reviewed/edited the manuscript. U.L. researched data. S.K. reviewed/edited the manuscript. M.B. and M.S. contributed to the discussion and reviewed/edited the manuscript. Guarantor: Dr Thomas Ebert is the guarantor of this work and, as such, had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Serum levels of fibroblast growth factor-21 are increased in chronic and acute renal dysfunction

submitted by
Janka Hindricks, born August 05th, 1986

prepared at the
Klinik und Poliklinik für Endokrinologie und Nephrologie, Universität Leipzig

mentored by
Prof. Dr. med. habil. Mathias Faßhauer

Submission August 2014

The prevalence of the Metabolic Syndrome (MetS) has been increasing globally for the past decades and the prevalence in Germany is above 20 %. The MetS is associated with an increased risk for cardiovascular morbidity and mortality. According to the NCEP definition, key aspects of the MetS include increases in serum lipids, elevated blood pressure, hyperglycemia, as well as central obesity. Out of these components, central obesity shows the strongest association with the MetS and weight loss therapy improves all MetS aspects, as well as its comorbidities. The development of central obesity usually occurs alongside with an increase in central adipose tissue mass. Adipose tissue functions as a complex endocrine organ and endocrine networks are dysregulated in obese patients. Adipose tissue produces a multitude of proteins – so-called adipokines – with various effects on human metabolism. These adipokines provide a potential link between body mass and the occurrence of metabolic disturbances.

In this context, FGF-21, a novel adipokine with beneficial effects on glucose and lipid profile in rodents, has been subject to thorough investigation. FGF-21 stimulates glucose uptake in preadipocytes independent from insulin. Furthermore, administration of the adipokine reduces body weight and improves insulin sensitivity in rodents and primates. In humans, FGF-21 levels are dysregulated in different metabolic disease states. Thus, FGF-21 concentrations are
elevated in patients with T2DM. In accordance with these findings, obese patients exhibit increased levels of the adipokine and the number of manifested MetS components predicts FGF-21 concentrations. A FGF-21-resistant state has been implied to be partially accountable for these findings. Despite extensive studies on FGF-21 regulation in human metabolic disease, data on FGF-21 elimination were rather limited. Therefore, the relation between the adipokine and human renal function in patients with chronic kidney disease (*study population 1*) and acute renal impairment (*study population 2*) has been investigated in the context of this dissertation. The adipokine was quantified in venous blood samples by commercial enzyme linked immunosorbent assay and correlated to anthropometric and biochemical markers of renal function, glucose and lipid homeostasis, as well as inflammation.

*Study population 1* (*n = 499*) was divided into 5 groups representing CKD stages 1 to 5 according to the KDOQI criteria. Median FGF-21 serum levels progressively increased from stage 1 to 5 (1: 86.4 ng/l; 2: 206.4 ng/l; 3: 289.8 ng/l; 4: 591.3 ng/l; 5: 1918.1 ng/l) while renal function assessed as eGFR progressively declined. In multivariate analysis, eGFR remained the strongest predictor for FGF-21 levels (*p < 0.001*).

In *study population 2* (*n = 32*) FGF-21 levels were quantified in patients undergoing unilateral partial or total nephrectomy shortly before surgery, and again within 30 hours after surgery. Median FGF-21 levels significantly increased after (325.0 ng/l) as compared to before surgery (255.5 ng/l; *p < 0.001*). Furthermore, relative changes of FGF-21 were independently and positively predicted by relative changes of creatinine in this cohort (*p < 0.001*).

Taken together, these results further support a strong relation between the adipokine FGF-21 and chronic renal dysfunction. Furthermore, first data regarding increased FGF-21 levels in acute kidney injury are presented. Our results are in accordance with the hypothesis that renal elimination of the adipokine is a major contributor to FGF-21 physiology. Animal studies are needed in order to further elucidate the role of elevated FGF-21 levels in kidney dysfunction and to define the extent to which serum FGF-21 elevation contributes to kidney disease comorbidities.
